Mean Value And Integral

In mathematics, the mean value theorem states, roughly, that for a given planar arc between two endpoints, there is at least one point at which the tangent to the arc is parallel to the secant through its endpoints. It is one of the most important results in real analysis. This theorem is used to prove statements about a function on an interval starting from local hypotheses about derivatives at points of the interval. More precisely, the theorem states that if

The mean is: (11 + 12 + 22 + 40 + 70 + 15,000) / 6 = 2526, a poor reflection of the center point. The median is resistant to outliers; the middle of this set is 26: in between the 22 and 40. Whether you use the mean or the median depends on lots of factors (including your instructor's preferences), but in general, don't use the average if you have outliers.

If the integral goes from a finite value a to the upper limit infinity, it expresses the limit of the integral from a to a value b as b goes to infinity. If the value of the integral gets closer and closer to a finite value, the integral is said to converge to that value; otherwise, it is said to diverge. When the limits are omitted, as in

Mean Value Theorem for Integrals. If f (x) f(x) f (x) is continuous on [a, b] [a, b] [a, b], then there exists a point c c c between a a a and b b b such that ∫ a b f (x) d x = f (c) (b - a). ∫int_[a]^b f(x) \, dx = f(c) (b-a). ∫ a b f (x) d x = f (c) (b - a). What does this have to do with the (actual) mean value theorem, other than the semblance of the indeterminate c c c?
